### ABSTRACT

Accurate estimation of leaf chlorophyll content ( $C_{ab}$ ) from remote sensing is of tremendous significance to monitor the physiological status of vegetation or to estimate primary production. Many vegetation indices (VIs) have been developed to retrieve  $C_{ab}$  at the canopy level from meter- to decameter-scale reflectance observations. However, most of these VIs may be affected by the possible confounding influence of canopy structure. The objective of this study is to develop methods for  $C_{ab}$  estimation using millimeter to centimeter spatial resolution reflectance imagery acquired at the field level.

Hyperspectral images were acquired over sugar beet canopies from a ground-based platform in the 400–1000 nm range, concurrently to  $C_{ab}$ , green fraction (GF), green area index (GAI) ground measurements. The original image spatial resolution was successively degraded from 1 mm to 35 cm, resulting in eleven sets of hyperspectral images. Vegetation and soil pixels were discriminated, and for each spatial resolution, measured  $C_{ab}$  values were related to various VIs computed over four sets of reflectance spectra extracted from the images (soil and vegetation pixels, only vegetation pixels, 50% darkest and brightest vegetation pixels). The selected VIs included some classical VIs from the literature as well as optimal combinations of spectral bands, including simple ratio (SR), modified normalized difference (mND) and structure insensitive pigment index (SIPI). In the case of mND and SIPI, the use of a blue reference band instead of the classical near-infrared one was also investigated. For the eleven spatial resolutions, the four pixel selections and the five VI formats, similar band combinations are obtained when optimizing VI performances: the main bands of interest are generally located in the blue, red, red-edge and near-infrared domains. Overall, mND<sub>blue</sub>[728, 850] defined as  $(R_{440} - R_{728})/(R_{440} + R_{850})$  and computed over the brightest green pixels obtains the best correlations with  $C_{ab}$  for spatial resolutions finer than 8.8 cm with a root mean square error of prediction better than 2.6  $\mu\text{g}/\text{cm}^2$ . Conversely, mND<sub>blue</sub>[728, 850] poorly correlates with variations in GF and GAI, thus reducing the risk of deriving non-causal relationships with  $C_{ab}$  that would actually be due to the covariance between  $C_{ab}$  and these canopy structure variables. As mND<sub>blue</sub>[728, 850] can be calculated from most current multispectral sensors, it is therefore a promising VI to retrieve  $C_{ab}$  from millimeter- to centimeter-scale reflectance imagery.

## 1. Introduction

Photosynthesis is one of the most important biological processes, allowing life on Earth through production of oxygen and organic matter (Ustin et al., 2009). Chlorophyll is one of the major plant pigments that contribute to the absorption of photosynthetically active radiation.

Quantifying chlorophyll temporal dynamics is therefore critical to monitor the vegetation physiological status or to estimate primary production (Blackburn, 2007, 1998). For this purpose, non-destructive estimation of leaf chlorophyll content (denoted  $C_{ab}$  hereafter) based on optical measurements has proven to be effective since  $C_{ab}$  drives most of the leaf reflectance and transmittance variabilities in the visible domain. A high  $C_{ab}$  retrieval accuracy is usually obtained at the leaf scale under controlled experimental conditions, e.g., using dedicated leaf clips measuring transmittance at a few wavelengths (Cerovic et al., 2012), or using hemispherical reflectance and/or transmittance

measurements to invert physical models such as PROSPECT ([Jacquemoud and Baret, 1990](#)) or to apply spectral indices ([Gitelson et al., 2003; Féret et al., 2011; le Maire et al., 2004](#)). The estimation of  $C_{ab}$  is more challenging at the canopy scale: soil reflectance and canopy architecture interact with leaf scattering properties to generate canopy reflectance. As a consequence, the effect of leaf composition may be confounded with those of canopy structural properties, making the inversion of canopy reflectance models an ill-posed problem ([Baret and Buis, 2008; Combal et al., 2003](#)): several combinations of green area index (GAI) and  $C_{ab}$  values may indeed correspond to similar canopy reflectance spectra in the visible domain, which increases the uncertainty of  $C_{ab}$  retrieval ([Baret and Buis, 2008](#)). Further, non-causal relationships between canopy reflectance and the targeted variable may be observed when structural and biochemical variables are correlated as reported by [Knyazikhin et al. \(2013\)](#). Effects of canopy structure and leaf composition should therefore be disentangled with great care when relating remote-sensing observations to foliar biochemistry ([Knyazikhin et al., 2013; Latorre-Carmona et al., 2014; Ustin, 2013](#)).

A first approach has been proposed to improve the  $C_{ab}$  estimation performance at the canopy level by maximizing the spectral sensitivity to foliar biochemistry while minimizing the effects of soil and vegetation structure. It consists in using a ratio vegetation index (VI), where the numerator is a  $C_{ab}$ -sensitive VI such as the Modified Chlorophyll Absorption Reflectance Index (MCARI) ([Daughtry et al., 2000](#)), and the denominator is a VI sensitive to canopy structure such as the Optimized Soil-Adjusted Vegetation Index (OSAVI) ([Rondeaux et al., 1996](#)). MCARI/OSAVI ([Daughtry et al., 2000](#)), TCARI/OSAVI ([Haboudane et al., 2002](#)) and derived versions of these two VIs ([Wu et al., 2008](#)) are examples of such combined indices, which have been demonstrated to provide accurate  $C_{ab}$  estimation results at the canopy level ([Kooistra and Clevers, 2016](#)).

Alternatively, a second approach consists in increasing the sensitivity to foliar biochemistry by optimizing the sun-sensor geometry: off-nadir measurements are generally more sensitive to leaf properties than nadir measurements ([Baret et al., 2010; Comar et al., 2012; Dorigo, 2012; Jacquemoud et al., 2009; Jay et al., 2017](#)). This is not only due to the higher proportion of vegetation seen by the sensor, but also to the large fraction of photons that have interacted with leaves before reaching the sensor ([Jacquemoud et al., 2009](#)). Further, the relative viewing azimuth angle affects the canopy reflectance sensitivity: measurements acquired in the backward direction, where shadows are minimized, generally exhibit a higher sensitivity to leaf biochemistry ([Dorigo, 2012; Jacquemoud et al., 2009; Jay et al., 2017](#)).

Finally, a third approach consists in focusing on the illuminated vegetation pixels when the spatial resolution is sufficient: this limits the detrimental influences of soil and canopy architecture and consequently strengthens the sensitivity to  $C_{ab}$  ([Moorthy et al., 2008; Zarco-Tejada et al., 2004, 2001](#)). Multi- and hyperspectral cameras operated from ground-based or low-altitude platforms provide a very high spatial resolution, ranging from a few millimeters to a few decimeters. However, most current retrieval methods do not fully exploit the new possibilities offered by such high spatial resolution imagery, thereby stimulating the need for new algorithms ([Elarab et al., 2015; Houborg et al., 2015](#)). The large variability of leaf orientation and illumination conditions observed at this scale induces strong variations in leaf radiance. For example, [Jay et al. \(2016\)](#) have proposed to invert the PROSPECT + COSINE (Clos-range Spectral ImagiNg of LEaves) model to map  $C_{ab}$  over individual leaves when the influence of surrounding elements is negligible. However, when individual leaves are submitted to the radiative transfer conditions that prevail in the canopy, the problem was not yet addressed. Most current VIs have been designed for leaf and canopy levels, and may therefore be suboptimal to handle the above-mentioned variations in leaf reflectance ([Bánkestad and Wik, 2016](#)).

This study focuses on  $C_{ab}$  estimation in sugar beet canopies using millimeter- to centimeter-resolution reflectance imagery. Hyperspectral images were acquired from a ground-based platform

and concurrent measurements of GAI and  $C_{ab}$  were completed. These data were used to design VIs dedicated to  $C_{ab}$  estimation that take advantage of such high spatial resolution imagery. Performances were compared to those obtained with several VIs of the literature for the range of spatial resolutions investigated.

## 2. Materials and methods

### 2.1. Field experiments

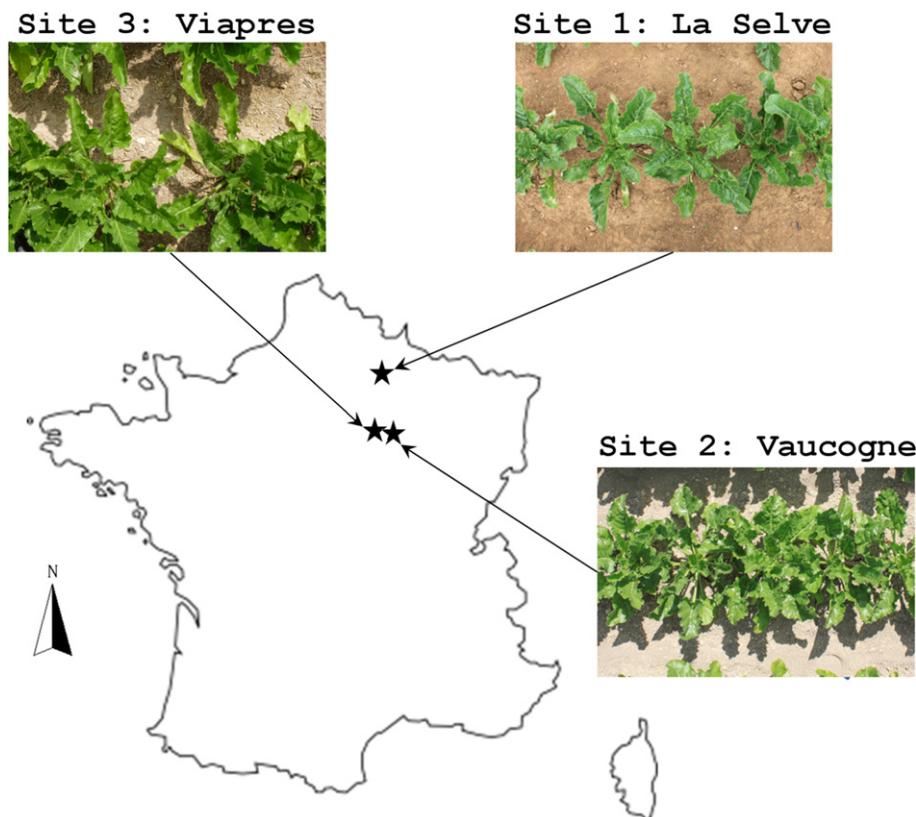

Field experiments were conducted in France in 2015 and 2016. Three study sites with different soil properties were considered as illustrated in [Fig. 1](#). A chalky soil was present at the “Vaucogne” (48°31'N, 4°21'E, denoted site 2) and “Viapres” (48°35'N, 4°2'E, denoted site 3) sites, while the “La Selve” site (49°35'N, 4°01'E, denoted site 1) was characterized by a loamy soil. The details of these field experiments are summarized in [Table 1](#). Seven sugar beet cultivars exhibiting differences in plant structure were submitted to variable levels of nitrogen fertilization. Rows were spaced 45 cm apart and plant population density was between 10 and 12 plants per square meter. So as to further increase the representativeness and heterogeneity of the data set, various phenological stages were considered during the 2015 and 2016 growing seasons, i.e., on June, 2–3 2015, June, 23–24 2015 and July, 26–27 2016. In particular, the crops considered in the 2016 experiment were carefully chosen so as to decorrelate  $C_{ab}$  and canopy structural properties. In total, the overall data set included 55 samples and encompassed a large variability due to differences in cultivars, nitrogen fertilizations, development stages, and soil and weather conditions.

### 2.2. Reflectance measurements

For each plot, an area corresponding to five consecutive plants along a row was imaged using a HySpec VNIR-1600 hyperspectral camera (Norsk Elektro Optikk, Norway) set up on a ground-based platform as shown in [Fig. 2](#). The push-broom camera pointed vertically downward from a 1.15 m distance to the bare soil. It measured the reflected radiation in 160 spectral bands ranging from 415 to 994 nm with a 3.7 nm spectral sampling interval and 4.5 nm full width at half maximum, and acquired successive scans of 1600 pixels along the row. The across-track field of view (FOV) was about 35 cm per scan at the ground level, providing a 0.02 cm across-track sampling distance. A 40% diffuse reflectance reference panel (Spectralon®, Labsphere) was used to measure the incoming solar irradiance while limiting possible saturation of the sensor. The reference panel was placed horizontally above the canopy to reduce the influence of possible vicinity effects. The HDRF (Hemispherical-directional Reflectance Factor) was finally computed by dividing the signal measured for each band and each pixel over the target by that measured over the reference panel and multiplying it by the reflectance of the reference panel provided by Labsphere (assuming the panel to be Lambertian). Completion of the scans over the 5 plants took a few seconds during which the incoming radiation was supposed to be stable. Measurements were collected around solar noon with solar zenith angle always lower than 36°. Illumination conditions differed between experiments, ranging from a clear blue sky to a fully overcast sky ([Table 1](#)).

### 2.3. $C_{ab}$ and canopy structure measurements

The leaf chlorophyll content was estimated for each plot after image acquisition over the same five plants. Six measurements per plant were made using a Dualex scientific +™ (Force-A, Orsay, France). This leaf clip measures leaf transmittance in a few wavebands from which  $C_{ab}$  is estimated using the relationship proposed by [Cerovic et al. \(2012\)](#) for dicotyledons, achieving an accuracy of around 4  $\mu\text{g}/\text{cm}^{-2}$ . Measurements were performed at different leaf levels to better consider the possible  $C_{ab}$  vertical gradient between leaves of different age or differently

**Fig. 1.** Locations of the three study sites and photographs of sugar beet canopies illustrating the encountered soil types (loamy soil for site 1 and chalky soil for sites 2 and 3).

located in the canopy. These thirty  $C_{ab}$  values were averaged to provide a single  $C_{ab}$  value per plot. After  $C_{ab}$  measurements, the five plants were collected and the area of each individual leaf measured using a photography-based technique. The GAI was finally obtained by multiplying the average leaf area per plant by the plant population density. In addition, the green fraction (GF, the fraction of green elements seen by the sensor in its view direction) was estimated from hyperspectral images using the discrimination method detailed in Section 2.4.2.

Inspection of the co-distributions between  $C_{ab}$  and GAI, and between  $C_{ab}$  and GF shows very poor correlations in both cases (Fig. 3). Incidentally, note the importance of the 2016 data that enable these correlations to be significantly reduced. The independency between  $C_{ab}$  and GAI (resp. GF) distributions prevents from obtaining spurious empirical relationships between VIs and  $C_{ab}$  that may be inherited from a more causal relationship between VIs and GAI (resp. GF).

#### 2.4. Processing of radiometric data

##### 2.4.1. Image spatial subsampling

The performance of  $C_{ab}$  estimation was evaluated over a range of spatial resolutions. The original spatial resolution of 0.02 cm was degraded to 0.1, 0.2, 0.4, 0.9, 1.8, 3.5, 4.4, 7, 8.8, 17.5 and 35 cm by

averaging over cells of  $N \times N$  pixels. This resulted in eleven sets of hyperspectral images as illustrated in Fig. 4.

##### 2.4.2. Discrimination of soil and vegetation

VIs were not only used to estimate  $C_{ab}$ , but also to discriminate green vegetation from senescent elements and soil. Preliminary tests (not further developed here for the sake of brevity, but illustrated in the figure provided in Supplementary material) demonstrated that the modified version of MCARI proposed by Wu et al. (2008) and defined as  $MCARI[705, 750] = [(R_{750} - R_{705}) - 0.2(R_{750} - R_{550})] \frac{R_{750}}{R_{705}}$  provided the best discrimination performance as compared to the other VIs investigated (Table 2). MCARI[705, 750] is designed to minimize the effects of soil and non-photosynthetic materials, and its discrimination capacity appeared to be little dependent on soil properties and illumination

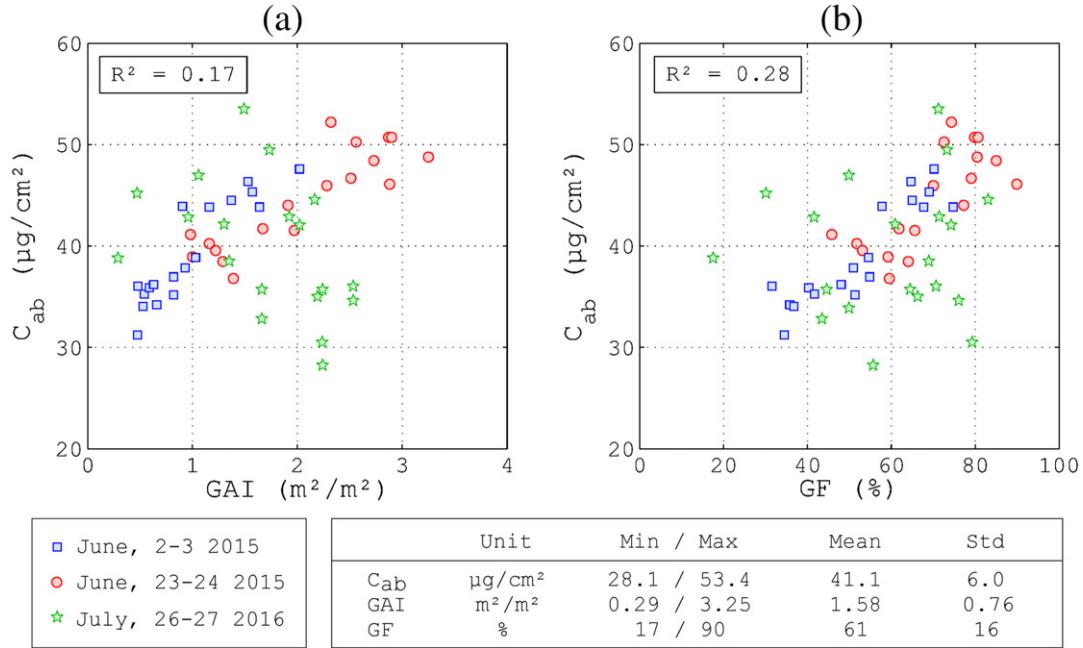

**Fig. 2.** Ground-based platform used for hyperspectral measurements.

**Table 1**

Characteristics of field experiments.  $\Theta_s$  is the sun zenith angle at the time of measurements.

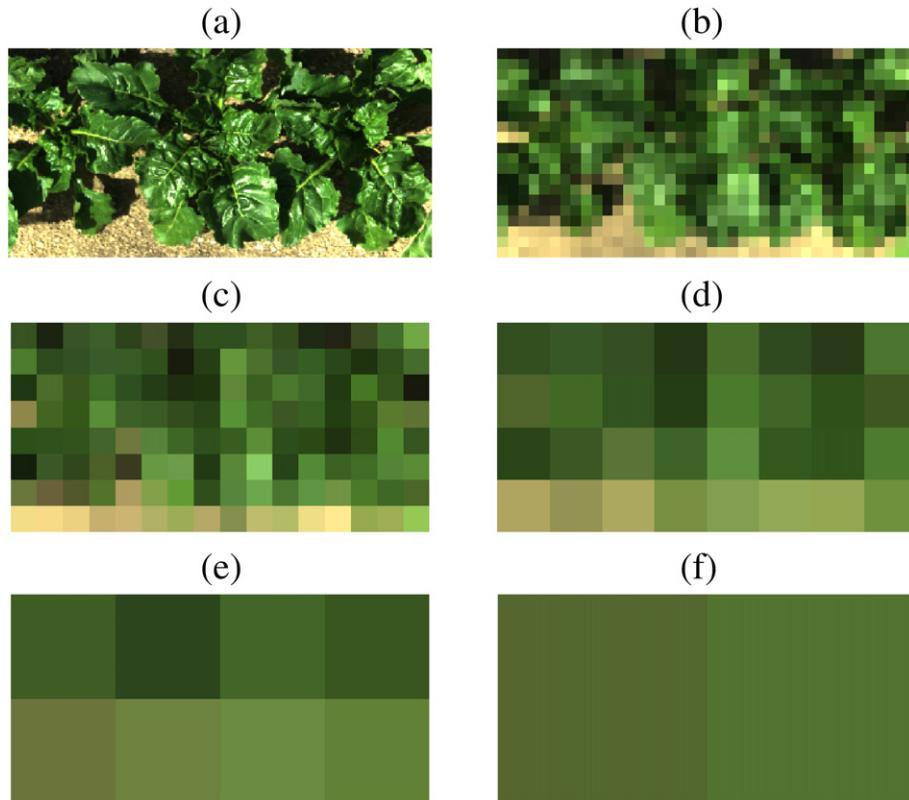

Date	Site	$\Theta_s$ (°)	Illumination	Cultivar no.	Number of samples
06/02/2015	2	36	Clear	1–3	9
06/03/2015	1	31	Cloudy	1–3	9
06/23/2015	1	29	Partly cloudy	1–3	9
06/24/2015	2	29	Clear	1–3	9
07/26/2016	3	33	Clear	4–6	8
07/27/2016	3	33	Partly cloudy	7	11

**Fig. 3.** C<sub>ab</sub>, GAI and GF reference measurements.

conditions. Further, as illustrated in Fig. 5b and g for strongly different soil properties and illumination conditions, a single threshold value of MCARI[705,750]=0.34 ensured accurate discrimination performance at the 0.1 cm spatial resolution, for which the fraction of mixed pixels was negligible (note that GF was estimated at this resolution). The fraction of mixed pixels significantly increased when the resolution

degraded, making the classification more difficult. The MCARI[705,750] threshold value was thus adjusted for each resolution investigated to keep the GF similar to that computed with the 0.1 cm spatial resolution. The threshold value was therefore increased as the spatial resolution degraded in order to compensate for the increase in the number of mixed pixels (Fig. 5).

**Fig. 4.** Gradual degradation of spatial resolution. Illustration for (a) 0.1 cm, (b) 1.8 cm, (c) 4.4 cm, (d) 8.8 cm, (e) 17.5 cm and (f) 35 cm.

## 2.5. $C_{ab}$ estimation

### 2.5.1. Selection of vegetation indices

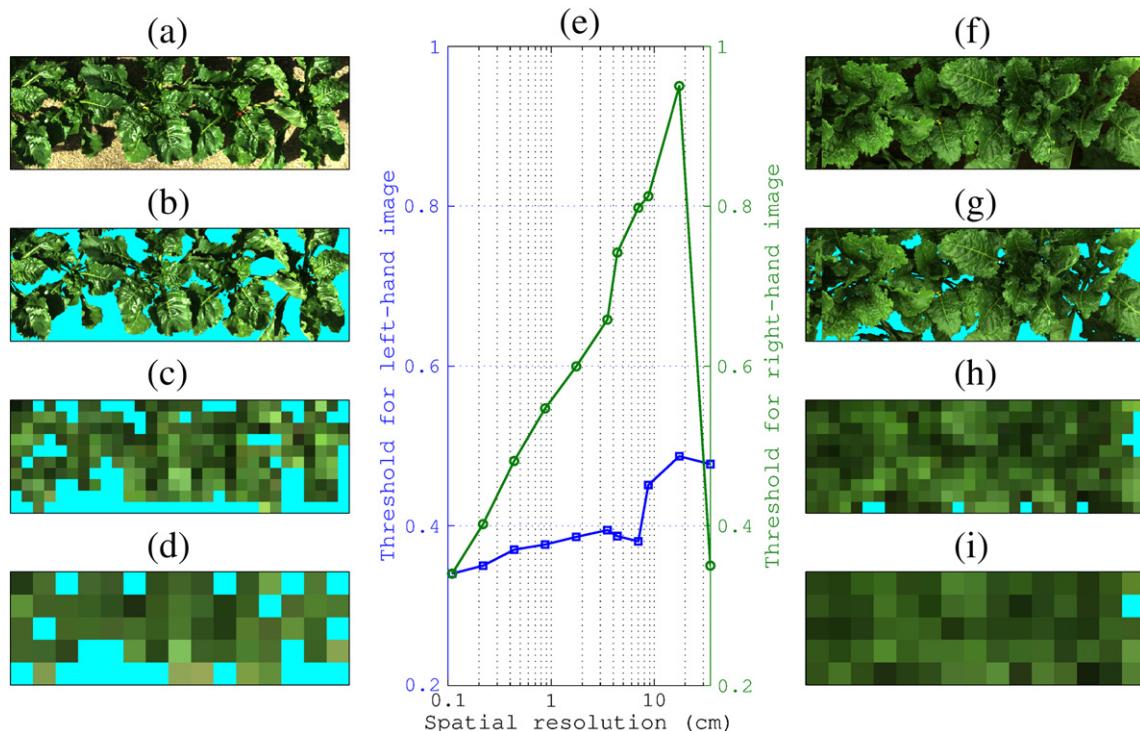

Several VIs were selected from the literature to estimate  $C_{ab}$ . All of them are ratios based on two or three wavebands located in the 400–900 nm spectral domain (Table 2). They are potentially sensitive to  $C_{ab}$ , GF, and GAI. VIs computed as ratios of linear combinations of bands present the advantage to minimize the possible influence of multiplicative factors, including slope effects and variations in illumination conditions when the radiance measurements on the reference panel and on the target are not performed concurrently. These ratio VIs may be split into three different categories as presented in Table 2.

The simplest one, SR (simple ratio), corresponds to the ratio of reflectance in two wavebands: a band, hereafter denoted  $\lambda_1$ , that is sensitive to both absorption by chlorophyll and scattering by leaf, and a reference band, denoted  $\lambda_{\text{ref}}$ , that is only sensitive to scattering in order to correct from this effect (Blackburn, 2007). For example,  $Cl_{\text{green}}$  and  $Cl_{\text{red-edge}}$  (Gitelson et al., 2006, 2005, 2003) are based on simple

ratios, and combine a near-infrared reference band with a band located in medium chlorophyll absorption domains to avoid saturation in  $C_{ab}$ . Both  $Cl_{\text{green}}$  and  $Cl_{\text{red-edge}}$  have been found to provide accurate estimates of  $C_{ab}$  at the leaf level (Gitelson and Merzlyak, 1994; Gitelson et al., 2003, 2006; Schlemmer et al., 2013) and canopy chlorophyll content at the canopy level (Gitelson et al., 2005; Clevers and Kooistra, 2012; Clevers and Gitelson, 2013; Schlemmer et al., 2013).

VIs from the second category are based on modified normalized difference ratios (mND), for which a third waveband, denoted  $\lambda_2$ , can be introduced at the denominator. Note that SR and mND are functionally related when  $\lambda_1 = \lambda_2$ , since  $mND = (1 - SR)/(1 + SR)$ . Alternatively, taking  $\lambda_2 \neq \lambda_1$  may increase the sensitivity to  $C_{ab}$  while reducing the impact of canopy structure and soil background properties.  $ND_{550}$  (Gitelson et al., 1996),  $ND_{705}$  (Gitelson and Merzlyak, 1994) and NDVI (Rouse et al., 1973) are examples of mND indices.

A simple modification of mND indices, i.e., SIPPI (structure insensitive pigment index) was proposed by Rondeaux and Vanderbilt (1993) and Penuelas et al. (1995) to decrease the confounding influence of leaf

**Fig. 5.** Discrimination results obtained from two contrasted situations, i.e., low GF with chalky soil and under sunny conditions (a), and large GF with loamy soil and under cloudy conditions (f). The same MCARI[705,750] threshold value is used for the finest (0.1 cm) spatial resolution (b, g). This threshold is then adjusted for coarser resolutions to keep the same GF (e). The resulting discrimination results are presented for 3.5 (c, h) and 7 cm (d, i) spatial resolutions. Masked soil pixels are colored in cyan. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

surface as well as canopy structure effects (Bousquet et al., 2005; Vigneau et al., 2011; Comar et al., 2014; Jay et al., 2016). For SIPI-like indices, various reference bands have been proposed: for example, Sims and Gamon (2002) have demonstrated that using a blue saturating waveband as reference within mSR (modified Simple Ratio) may increase the  $C_{ab}$  estimation performance as compared to SR indices. MTCI (MERIS Terrestrial Chlorophyll Index) proposed by Dash and Curran (2004) is also a SIPI-like index, where the three bands used are conveniently located in the red-edge spectral domain, the reference band (709 nm) being close to the red one.

Because of the diversity of bands used to compute the three types of VIs as outlined in Table 2, the data set presented in Section 2 was used to find optimal sets of wavebands in the case of millimeter- to centimeter-scale reflectance imagery of sugar beet canopies. Similarly to Penuelas et al. (1995) and Inoue et al. (2012),  $C_{ab}$  prediction performance of these three VIs were evaluated for every possible combination of  $\lambda_1$  and  $\lambda_2$  bands between 415 and 900 nm by 3.7 nm step.  $C_{ab}$  prediction performances were assessed using the Spearman's rank correlation coefficient, denoted  $\rho$ . As compared to using the usual Pearson's coefficient,  $R$ , using  $\rho$  reduces the influence of possible non-linearities between VIs and  $C_{ab}$  as well as between Dualex readings and actual  $C_{ab}$  values. In the case of SR that uses only two wavebands, the reference band was also varied systematically from 415 to 900 nm, and SR indices were thus noted  $SR[\lambda_1, \lambda_2]$ . In the cases of mND and SIPI indices, as the reference waveband should be insensitive to  $C_{ab}$  variations over the considered  $C_{ab}$  range, it was set either to near infrared (850 nm) or to blue (440 nm). The corresponding VIs were thus noted respectively  $mND_{nir}[\lambda_1, \lambda_2]$  and  $SIPI_{nir}[\lambda_1, \lambda_2]$  if  $\lambda_{ref} = \lambda_{nir} = 850$  nm, and  $mND_{blue}[\lambda_1, \lambda_2]$  and  $SIPI_{blue}[\lambda_1, \lambda_2]$  if  $\lambda_{ref} = \lambda_{blue} = 440$  nm. Note that, although the atmosphere has lesser influence on the measured signal when using low altitude sensors (e.g., ground- or tower-based, or embedded on unmanned aerial vehicles (UAVs)) instead of classical satellite- and airborne sensors, the reflected radiation in the blue domain may strongly vary with changes in illumination conditions caused by atmospheric absorption and scattering. This implies that the use of  $mND_{blue}[\lambda_1, \lambda_2]$  and  $SIPI_{blue}[\lambda_1, \lambda_2]$  requires a particular attention to properly convert the measured radiance into reflectance. Also, if necessary due to the lower sensitivity of CCD sensors in the blue region, the signal-to-noise ratio may be increased by aggregating a few wavebands around 440 nm.

### 2.5.2. Estimation procedure

Every tested VI was related to the measured  $C_{ab}$  values using the 55 images, the strength of the relationship being quantified based on the squared Spearman's correlation coefficient,  $\rho^2$ . This process was applied for each spatial resolution using four subsets of reflectance spectra. (1) For the first subset, all pixels were used, i.e., including both soil and vegetation parts. (2) In the second subset, only green pixels were used. These vegetation pixels were then sorted according to their brightness level computed as the average reflectance value in the 770–900 nm spectral domain. This allowed us to define the two last subsets, corresponding to (3) the 50% darkest green pixels, and (4) the 50% brightest green pixels. Such pixel selections influence the impact of canopy structure on VIs as reported by Zarco-Tejada et al. (2001). Furthermore, two strategies were considered to compute the VI average value over selected pixels: either (1) reflectance spectra were first averaged over all pixels of the subset and the VI was then calculated, or (2) the VI was first computed for each pixel of the subset and the resulting VI values were then averaged. As VIs are generally non-linear functions of reflectance, these two strategies may lead to different results if the images are heterogeneous (Steven et al., 2015). The performance of  $C_{ab}$  estimation were thus evaluated for the eleven spatial resolutions, the four subsets of pixels and the two VI averaging strategies, resulting into 88 regressions for each VI. Ultimately, linear and best non-linear relationships between  $C_{ab}$  and best VIs were determined. Prediction performances for each relationship were then quantified based on the coefficient of

determination ( $R^2$ ) and the root mean square error of prediction (RMSEP), both being estimated using a leave-one-out cross-validation process because of the relatively small number of images available.

In addition, the same procedure was applied for GF and GAI estimations since the considered VIs are also potentially sensitive to these structural variables.

## 3. Results and discussion

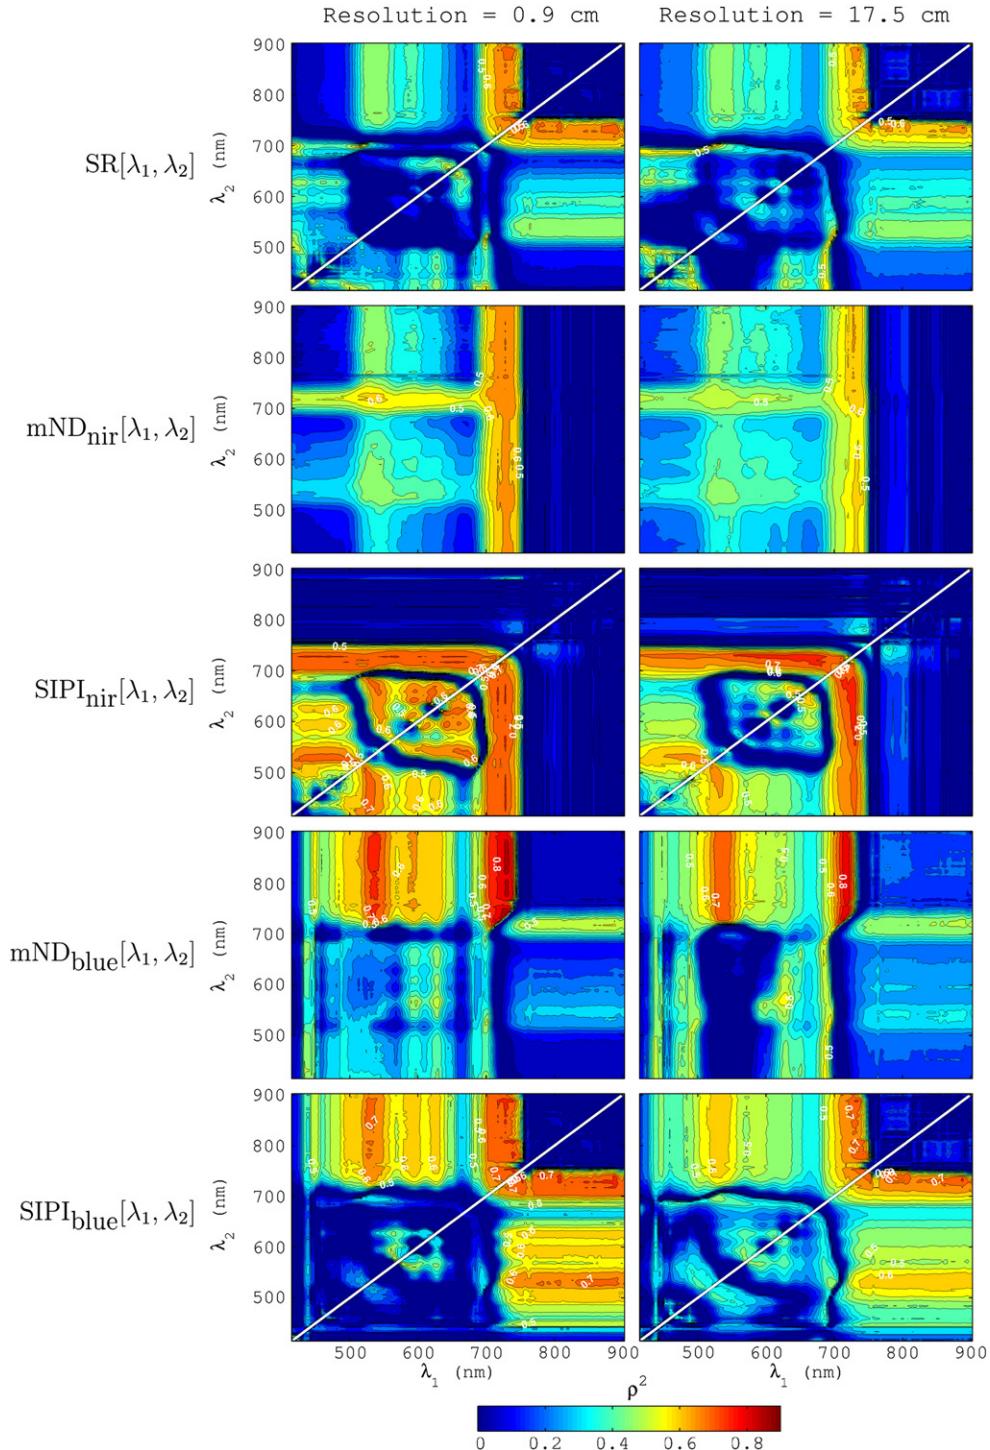

In the following, the selection of optimal sets of wavebands to compute the VIs is first investigated. These optimized VIs are then compared to the classical ones presented in Table 2 based on their relationships with  $C_{ab}$ , GF and GAI, especially emphasizing the effects of spatial resolution and pixel selections.

### 3.1. Optimal band selection for $C_{ab}$ estimation from vegetation indices

Because of the multidimensional aspect of this study and the associated complexity for reporting the results in an exhaustive way, emphasis is put on 0.9 cm and 17.5 cm spatial resolutions that illustrate two contrasted situations. Further, only the results obtained by computing VIs from average reflectance spectra of vegetation pixels are presented. Very similar results were observed for the other spatial resolutions, subsets of pixels and when computing VIs by averaging pixel-level VI values. For the sake of brevity, these results are not presented in this article.

For every VI, similar patterns of  $\rho^2$  squared Spearman's correlation coefficient are observed for the two spatial resolutions investigated (Fig. 6). The maximum values are obtained for very similar combinations of  $[\lambda_1, \lambda_2]$  wavebands. However, the 0.9 cm spatial resolution provides generally higher  $\rho^2$  values as well as slightly broader patterns of high correlations as compared to the 17.5 cm resolution. The largest difference between the two spatial resolutions occurs for the  $SIPI_{nir}$  in the yellow to red domains where soil and vegetation reflectances show the largest contrast. In this case, the higher proportion of mixed pixels significantly degrades the correlations with  $C_{ab}$ . Symmetrical patterns are observed for SR and SIPI indices, since  $SR[\lambda_1, \lambda_2] = 1/SR[\lambda_2, \lambda_1]$  and  $SIPI[\lambda_1, \lambda_2] = 1/SIPI[\lambda_2, \lambda_1]$ . Conversely, non-symmetrical patterns are observed for mND indices that do not verify this property.

For  $SR[\lambda_1, \lambda_2]$ , the best performances are obtained taking  $\lambda_1$  in the red-edge (between 710 and 735 nm) and  $\lambda_2$  having a longer wavelength. The highest correlation is observed for  $SR[732, 884]$ , which is close to the  $CI_{red\ edge}$  proposed by Gitelson et al. (2005, 2003, 2006). Selecting a red-edge band actually increases the sensitivity to  $C_{ab}$  variation for high  $C_{ab}$  values, i.e., it minimizes the saturation effect. For  $mND_{nir}[\lambda_1, \lambda_2]$ , the best performances are obtained choosing  $\lambda_1$  in the red-edge and  $\lambda_2$  in the red-edge and near infrared domains, i.e.,  $R_{\lambda_2} \approx -R_{\lambda_{nir}}$ . For such waveband combinations, we have  $mND_{nir}[\lambda_1, \lambda_{nir}] \approx 1 - SR[\lambda_1, \lambda_{nir}] \approx CI_{red\ edge}$ . A convergence is thus reached between these two generic VIs when optimizing the set of wavebands for  $C_{ab}$  estimation. Anyway, the highest correlation is obtained for  $mND_{nir}[732, 850]$ . For  $SIPI_{nir}[\lambda_1, \lambda_2]$ , the best performances are observed for  $\lambda_1$  in the red-edge and  $\lambda_2$  in the green to red domains, the optimal combination being  $SIPI_{nir}[728, 670]$ . This VI is similar to the original SIPI (Penuelas et al., 1995) with the exception of the use of a red-edge band at the numerator instead of a blue band, which reduces possible saturation effects for the considered  $C_{ab}$  range. Note that no bands are selected in the near-infrared range since the reference band is already in this domain. For  $mND_{blue}[\lambda_1, \lambda_2]$ , the best performances are observed for  $\lambda_1$  in the red-edge and  $\lambda_2$  in the red-edge and near-infrared domains. Note that taking  $\lambda_1$  in the green range (around 533 nm) also provides strong correlations, especially at 0.9 cm spatial resolution. In addition to the blue band used as a reference, the bands showing the largest contrast in chlorophyll absorption coefficients are selected. Unlike the other VIs tested, the best  $C_{ab}$ -sensitive waveband slightly differs between the two spatial resolutions, ranging from 728 nm at 0.9 cm to 717 nm at

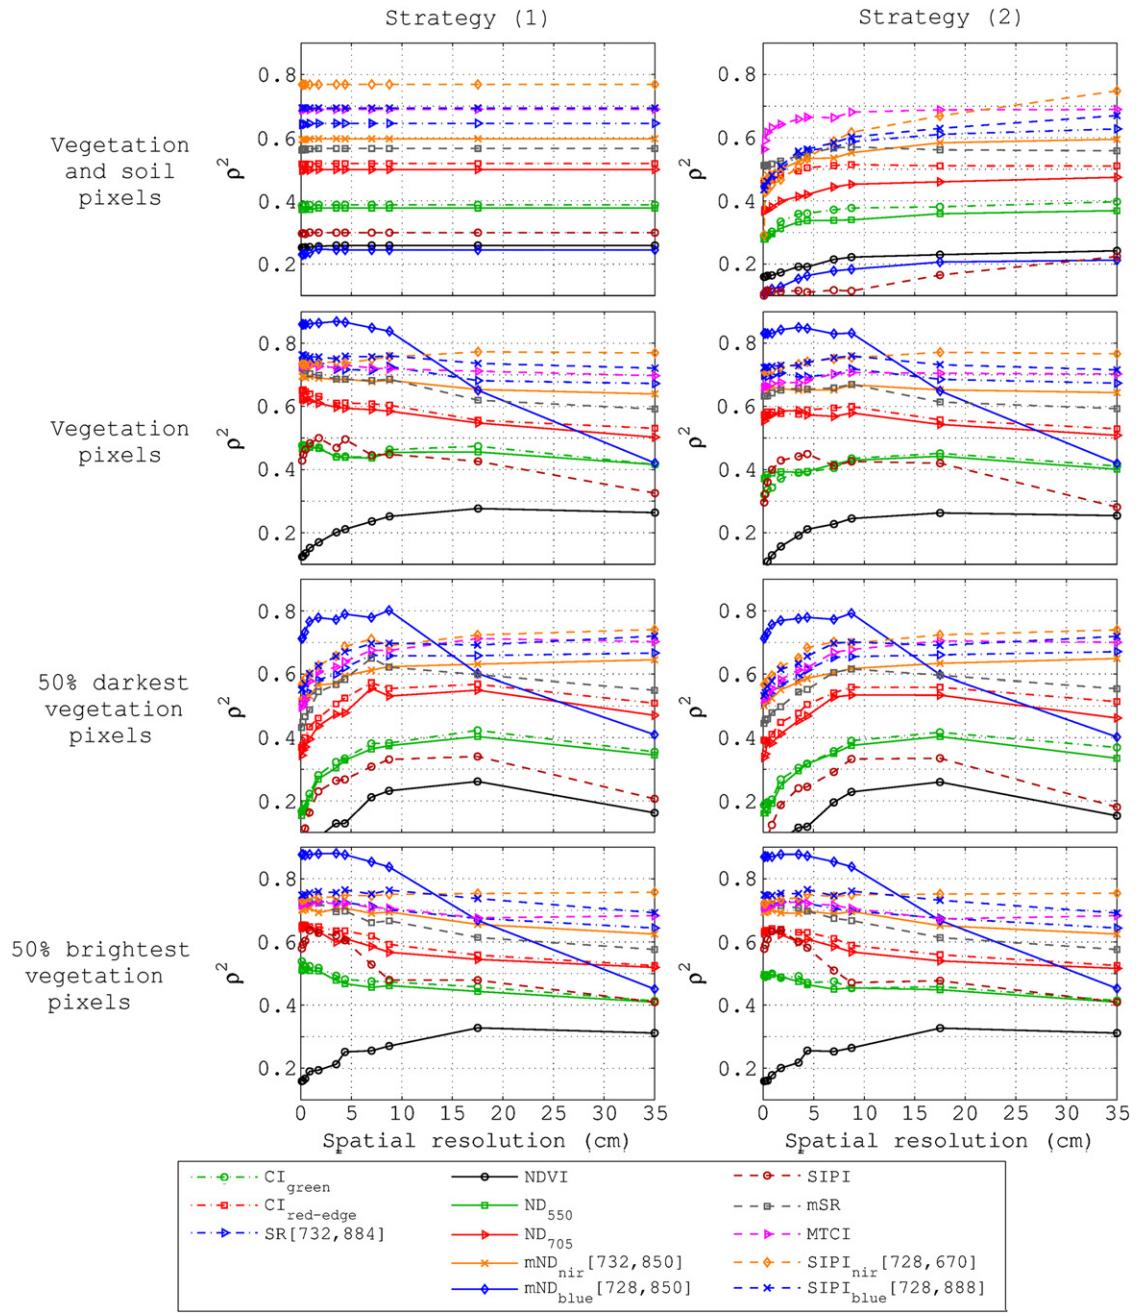

**Fig. 6.** Squared Spearman's correlation ( $\rho^2$ ) obtained between VIs and  $C_{ab}$  as a function of  $\lambda_1$  and  $\lambda_2$  wavebands. VIs are computed from average reflectance spectra of vegetation pixels for the 0.9 cm (left-hand column) and 17.5 cm (right-hand column) spatial resolutions. The five generic VIs are considered, i.e.,  $SR[\lambda_1, \lambda_2]$ ,  $mND_{nir}[\lambda_1, \lambda_2]$ ,  $SIPI_{nir}[\lambda_1, \lambda_2]$ ,  $mND_{blue}[\lambda_1, \lambda_2]$ , and  $SIPI_{blue}[\lambda_1, \lambda_2]$  from top to bottom. The color scale is the same for the five VIs and the two spatial resolutions.

17.5 cm. Since the best performances are obtained for  $\lambda_1 = 728$  nm,  $mND_{blue}[728, 850]$  is selected for further analysis. Finally, for  $SIPI_{blue}[\lambda_1, \lambda_2]$ , the maximum correlations are obtained taking  $\lambda_1$  in the red-edge and  $\lambda_2$  in the NIR plateau for the same reasons as those involved for  $mND_{blue}$ . The optimal waveband combination is  $SIPI_{blue}[728, 888]$ , whose expression mainly differs from the mSR index proposed by [Sims and Gamon \(2002\)](#) by the use of a longer  $C_{ab}$ -sensitive waveband.

### 3.2. Sensitivity to $C_{ab}$

The VI sensitivity to  $C_{ab}$  (in terms of  $\rho^2$ ) is shown in Fig. 7 for the classical VIs presented in Table 2 as well as the five optimized VIs designed in Section 3.1. These VIs are computed for the eleven spatial resolutions, the four subsets of pixels and the two strategies to compute the VIs.

Comparing the two strategies for computing VI values from images shows that the differences mainly depend on the level of heterogeneity

**Fig. 7.** Squared Spearman's correlation ( $p^2$ ) between VIs and  $C_{ab}$  measured over the 55 plots as a function of spatial resolution. In the left-hand column, VIs are computed from the average reflectance spectra of considered pixels (strategy 1), while in the right-hand column, VIs are computed by averaging pixel-level VI values (strategy 2). For both strategies, the four subsets of pixels are tested (vegetation and soil pixels, vegetation pixels, 50% darkest or brightest green pixels).

within the considered pixels. The heterogeneity increases as the spatial resolution increases and the pixel selection becomes less restrictive (in order, 50% darkest or brightest green pixels, green pixels, all the pixels). When the level of heterogeneity is the largest, as when considering all the pixels in the case of high resolution (Fig. 7, line 1), averaging first the reflectance values over the pixels and then computing the VI (Strategy 1) provides better  $C_{ab}$  estimation performances than Strategy 2 (averaging the VI values computed for each individual pixel). This may be due to the fact that averaging the reflectances put more weight on the brightest pixels that bear more reliable information on  $C_{ab}$  as demonstrated later. Conversely, computing first the VIs at the pixel level may lead to unrealistic VI values when the pixels have low reflectance values: since VIs are computed as ratios, low values in the denominator will provide unstable values. Note that, since the average reflectance

value in the image does not depend on spatial resolution, the performances do not change with spatial resolution when computing VIs from the average reflectance spectra over all the pixels (Fig. 7, top left-hand plot). When the distribution of pixel values is reduced as in the case of medium to coarse spatial resolution for a restricted selection of pixels (green pixels, 50% darkest or brightest green pixels), the two strategies lead to very similar results (Fig. 7, lines 2–4). Only Strategy 1 will therefore be considered in the following since it provides either best or equal  $C_{ab}$  estimation performances as Strategy 2.

When all the pixels are considered (Fig. 7, line 1), the best-performing VI is  $SIPI_{nir}[728, 670]$  ( $\rho^2 = 0.77$ ), followed by  $SIPI_{blue}[728, 888]$  and  $MTCI$  ( $\rho^2 = 0.69$ ). A substantial improvement is observed for every VI except  $NDVI$  when considering only vegetation pixels, especially for spatial resolutions finer than 8.8 cm.

$mND_{blue}[728,850]$  obtains significantly higher correlations than other VIs with  $\rho^2$  ranging from 0.84 to 0.87 for resolutions finer than 8.8 cm. Again, the SIPI VIs show good correlations, with  $SIPI_{blue}[728,888]$ ,  $SIPI_{nir}[728,670]$  and MTCI achieving  $\rho^2$  close to 0.74 for the finest resolutions. Incidentally, it is worth noting that, even if MTCI was originally designed for estimating canopy chlorophyll content from low-resolution satellite sensors (Dash and Curran, 2004), the good performances obtained here are consistent with those observed in previous studies dealing with leaf chlorophyll content estimation from higher resolution remote sensing (Haboudane et al., 2008; Hunt et al., 2012; Jay et al., 2017). While the performances obtained with most VIs remain nearly stable when the resolution degrades, those obtained with  $mND_{blue}[728,850]$  drop down to  $\rho^2=0.42$  at 35 cm spatial resolution. This indicates that  $mND_{blue}[728,850]$  is very sensitive to the soil influence observed in mixed pixels. In the case of coarse spatial resolutions for which vegetation and soil cannot be accurately discriminated, using a shorter wavelength more sensitive to  $C_{ab}$  for  $\lambda_1$  is expected to improve the performances by mitigating the soil influence as discussed earlier (Fig. 6).

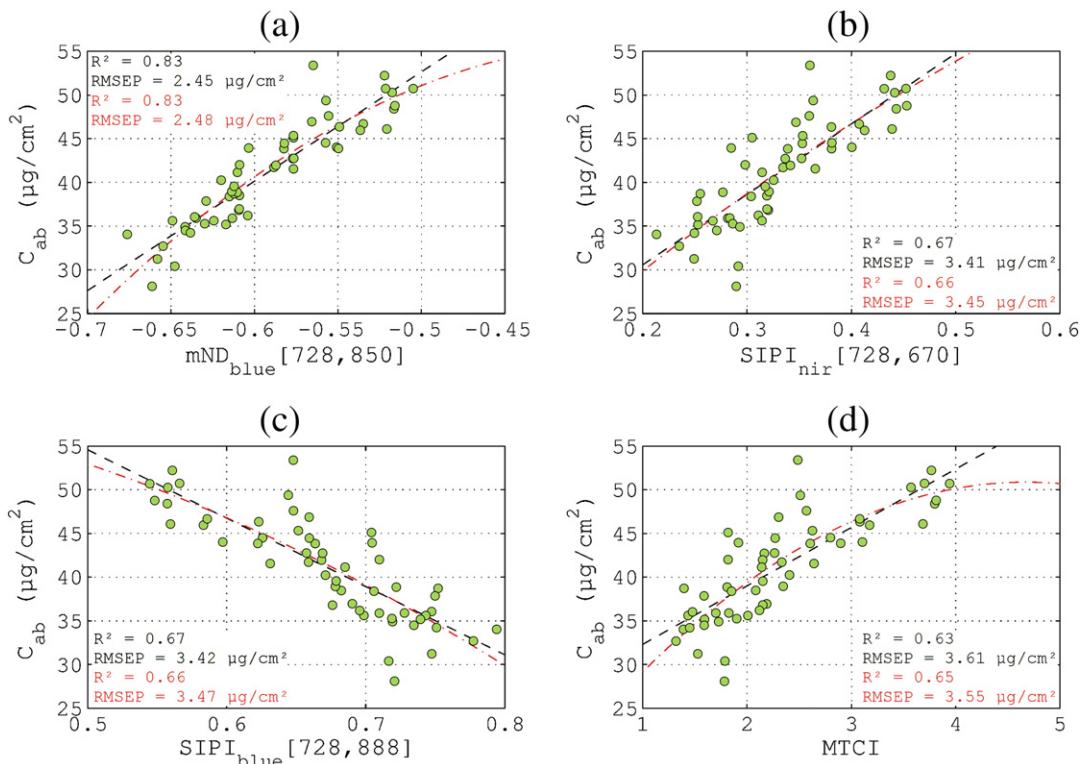

Considering the 50% brightest green pixels (Fig. 7, line 4) generally improves the performances of  $C_{ab}$  estimation for every resolution as compared to using all the green pixels (Fig. 7, line 2). In particular,  $mND_{blue}[728,850]$  reaches  $\rho^2=0.88$  for resolutions finer than 4.4 cm, while  $SIPI_{blue}[728,888]$  and  $SIPI_{nir}[728,670]$  led to  $\rho^2=0.76$  and  $\rho^2=0.74$  respectively. The benefit of considering only the brightest green pixels for  $C_{ab}$  estimation is in agreement with previous findings (Moorthy et al., 2008; Zarco-Tejada et al., 2004, 2001). Conversely, using the 50% darkest pixels results in lower correlations, especially for the highest spatial resolutions. For those pixels, the incoming radiation contains a higher proportion of photons that have already interacted with the canopy before reaching the considered leaves. This may make the illumination conditions locally very variable, leading to lower correlations with  $C_{ab}$ .

The best cases are analyzed in more detail to better quantify their performances (Fig. 8). They correspond to  $mND_{blue}[728,850]$ ,  $SIPI_{blue}[728,888]$ ,  $SIPI_{nir}[728,670]$  and MTCI computed from the average reflectance spectra of the 50% brightest green pixels observed at the 3.5 cm spatial resolution.  $mND_{blue}[728,850]$  achieves the best performances with  $R^2=0.83$  and  $RMSEP=2.45 \mu\text{g}/\text{cm}^2$  (i.e., 9.6% of  $C_{ab}$  range) using a linear regression model, while the non-linear regression model does not improve the results. The three other best VIs lead to significantly lower estimation performances, ranging from  $R^2=0.67$  and  $RMSEP=3.41 \mu\text{g}/\text{cm}^2$  (13.4%) for  $SIPI_{nir}[728,670]$  to  $R^2=0.65$  and  $RMSEP=3.55 \mu\text{g}/\text{cm}^2$  (14.0%) for MTCI. These RMSEP values are about 40% higher than that obtained with  $mND_{blue}[728,850]$ . Note that these RMSEP values should be reassessed by using more accurate  $C_{ab}$  measurements as obtained from a pigment extraction method instead from transmittance-based Dualex measurements.

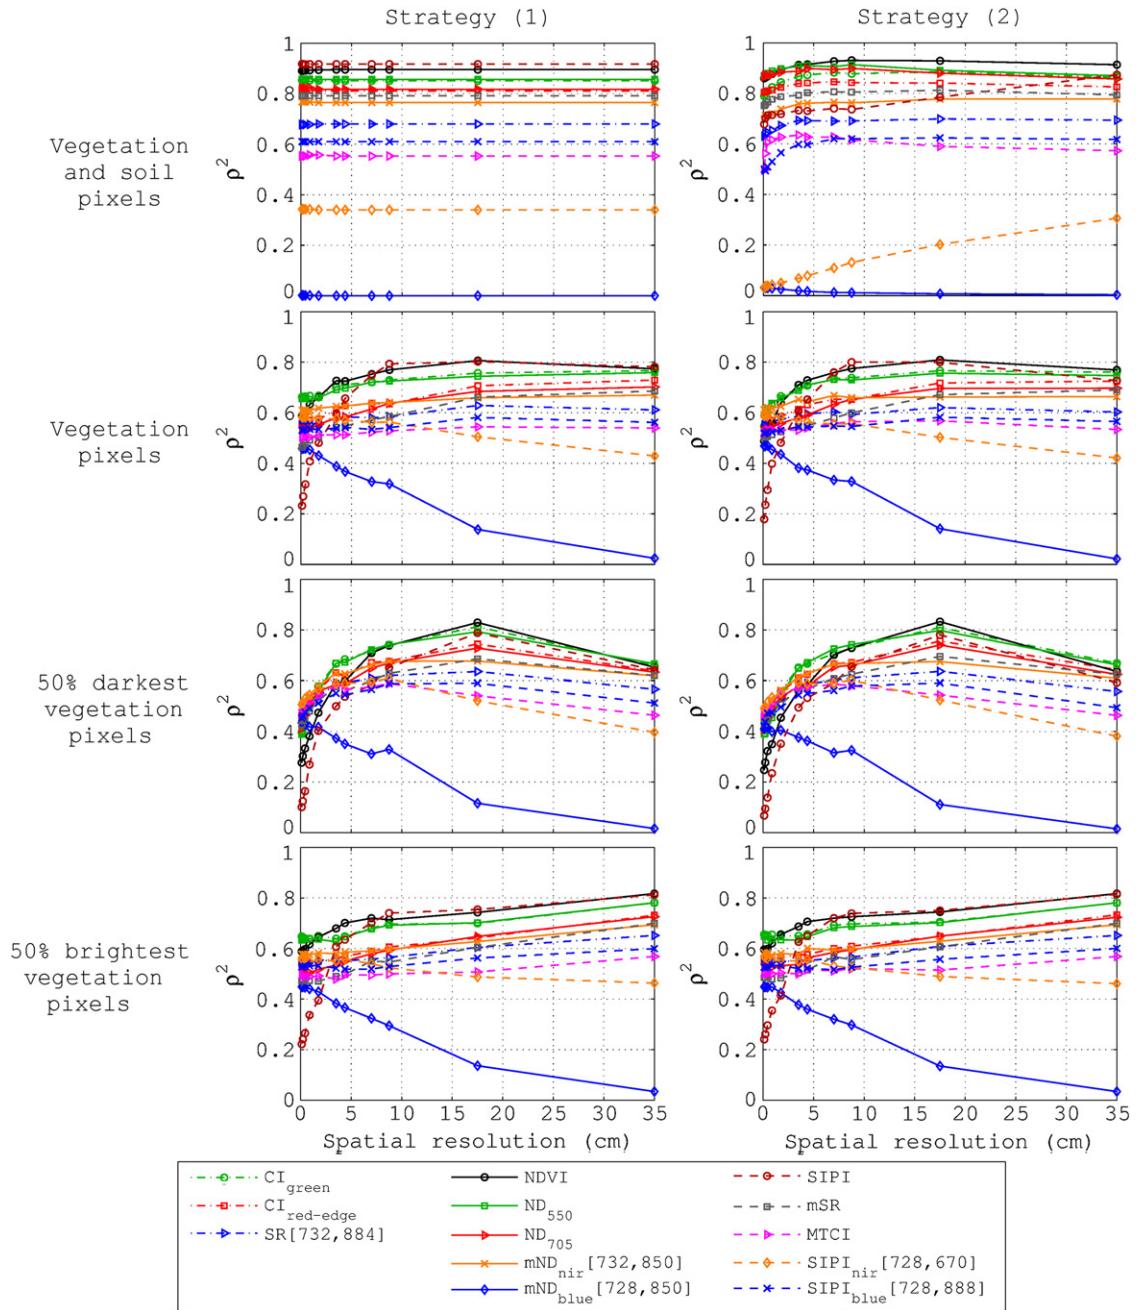

### 3.3. Sensitivity to GF and GAI

As mentioned earlier, VIs may be simultaneously sensitive to variations in  $C_{ab}$  and canopy structural variables such as GF or GAI. The effect of leaf biochemical composition must therefore be carefully disentangled from that of structural variables.

For this purpose, the correlation between the tested VIs and GF (Fig. 9) or GAI (Fig. 10) was investigated. For both structural variables, the performances of the two strategies to compute the VIs similarly depend on the level of heterogeneity in the pixel selection. However, unlike for  $C_{ab}$ , when the heterogeneity is the largest, as when considering all the pixels at the highest resolutions, averaging the pixel-level VI values (Strategy 2) generally provides slightly better correlations with both GF and GAI than computing the VI from the average reflectance spectra (Strategy 1). As observed for  $C_{ab}$  (Fig. 7), Strategy 2 enhances the influence of the heterogeneity: the latter contains little information about  $C_{ab}$  variations while being strongly driven by the canopy structure,

**Fig. 8.** Relationships between  $C_{ab}$  and (a)  $mND_{blue}[728,850]$ , (b)  $SIPI_{nir}[728,670]$ , (c)  $SIPI_{blue}[728,888]$ , and (d) MTCI. The spatial resolution is 3.5 cm, and VIs are computed from average reflectance spectra of the 50% brightest vegetation pixels. For each VI, the prediction performances obtained using linear (in black) and best non-linear (second-degree polynomials, in red) regressions are shown. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

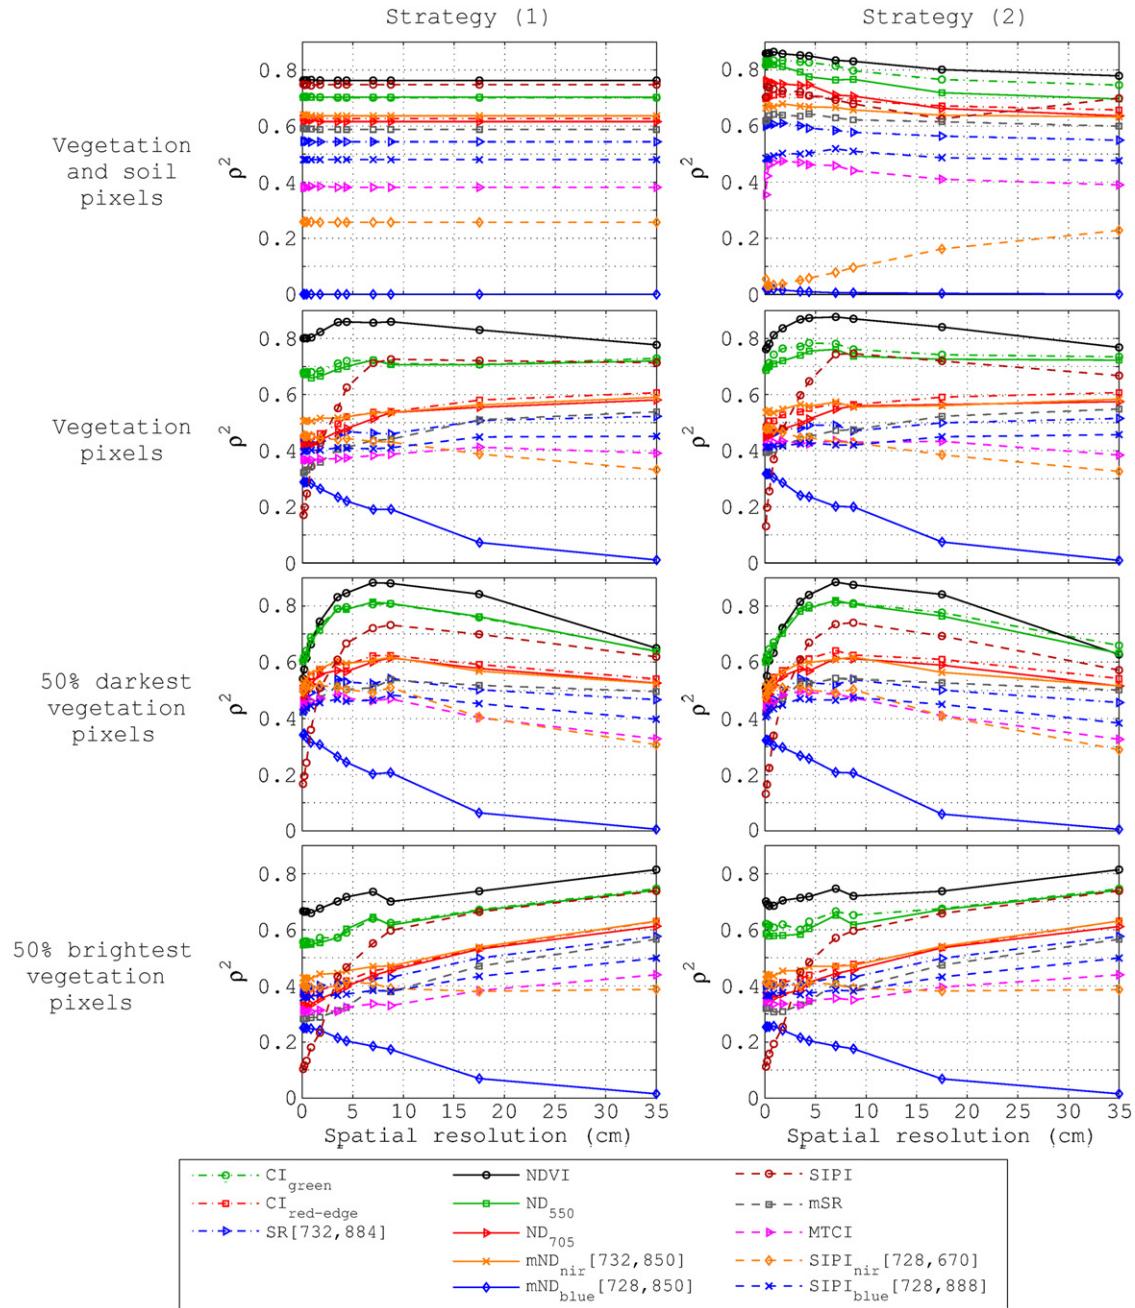

**Fig. 9.** Squared Spearman's correlation ( $\rho^2$ ) between VIs and GF measured over the 55 plots as a function of spatial resolution. In the left-hand column, VIs are computed from the average reflectance spectra of considered pixels (strategy 1), while in the right-hand column, VIs are computed by averaging pixel-level VI values (strategy 2). For both strategies, the four subsets of pixels are tested (vegetation and soil pixels, vegetation pixels, 50% darkest and brightest vegetation pixels).

e.g., through the proportion of soil and vegetation pixels as well as that of shaded and illuminated pixels. This explains why Strategy 2 provides more accurate retrievals of these structural variables as compared to Strategy 1. However, when the distribution of pixels is reduced, very similar results are obtained for the two strategies (Fig. 9 and 10, lines 2–4), similarly to what is observed for  $C_{ab}$ . Only Strategy 2 will therefore be considered in the following since it provides either best or equal GF and GAI estimation performances as Strategy 1.

In the case of GF estimation, strong correlations ( $\rho^2 \geq 0.6$ ) are generally obtained with all tested VIs except  $mND_{blue}[728, 850]$  and  $SIPI_{nir}[728, 670]$  when all the pixels are considered (Fig. 9, line 1). NDVI achieves the best performances for spatial resolutions close to 8 cm ( $\rho^2 = 0.93$ ). Unlike for  $C_{ab}$ , no further improvement is observed

when using only vegetation pixels (Fig. 9, lines 2–4) since, by definition, GF relates to the relative proportions of vegetation and soil.

In the case of GAI estimation when considering all the pixels, the best VIs are NDVI ( $\rho^2 = 0.86$ ) followed by  $CI_{green}$  and  $ND_{550}$  ( $\rho^2 = 0.83$ ) for spatial resolutions finer than 1.8 cm because of the beneficial influence of pure soil pixels (Fig. 10, line 1). For similar reasons as for GF estimation, focusing on green pixels generally decreases the performances for most resolutions and tested VIs (Fig. 10, lines 2–4), especially when considering the 50% brightest green pixels at the finest resolutions for which the impact of canopy structure is minimum. The main exceptions occur for resolutions around 8 cm with NDVI,  $CI_{green}$ ,  $ND_{550}$  and  $SIPI$ , whose performances achieved when considering the 50% darkest green pixels improve as compared to using all the pixels.

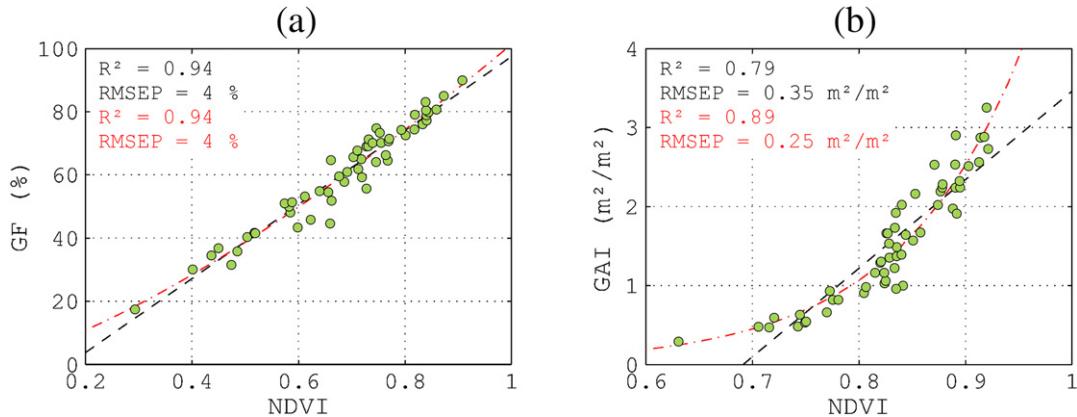

**Fig. 10.** Squared Spearman's correlation ( $\rho^2$ ) between VIs and GAI measured over the 55 plots as a function of spatial resolution. In the left-hand column, VIs are computed from the average reflectance spectra of considered pixels (strategy (1)), while in the right-hand column, VIs are computed by averaging pixel-level VI values (strategy (2)). For both strategies, the four subsets of pixels are tested (vegetation and soil pixels, vegetation pixels, 50% darkest and brightest vegetation pixels).

The best correlation over all pixel selections is actually obtained by NDVI at the 7 cm spatial resolution ( $\rho^2 = 0.88$ ). This may be due to the fact that this combination resolution/pixel selection offers the best compromise to maximize the sensitivity to canopy structure variations (maximum for the finest resolutions) while minimizing NDVI saturation (minimum for the coarsest resolutions).

These results thus demonstrate the specificities associated with each VI: most tested VIs appear to be mainly related to GF and GAI while  $mND_{blue}[728, 850]$  and to a lesser extent  $SIPI_{nir}[728, 670]$  are strongly related to  $C_{ab}$  and almost not sensitive to the structural variables. Such a result is of tremendous importance since it demonstrates that the sensitivity of  $mND_{blue}[728, 850]$  to  $C_{ab}$  will not derive from non-causal relationships due to possible covariance between  $C_{ab}$  and canopy structure observed over the training data set.

The best cases observed in Figs. 9 and 10 are further detailed in Fig. 11 to quantify their performances. In the case of GF estimation, the best case corresponds to NDVI computed from all the pixels observed at the 8.8 cm resolution (Fig. 11.a). It obtains  $R^2 = 0.94$  and  $RMSEP = 4\%$  (5.4% of the GF range) using either linear or non-linear regression models. In the case of GAI estimation, the best case corresponds to NDVI computed over the 50% darkest green pixels observed at the 7 cm resolution (Fig. 11.b). While using a linear model leads to reasonable estimation results ( $R^2 = 0.79$  and  $RMSEP = 0.35 \text{ m}^2/\text{m}^2$  corresponding to 11.8% of the GAI range), using an exponential model significantly improves the performance to take into account the saturation occurring for high GAI values, as suggested by Baret and Guyot (1991) ( $R^2 = 0.89$  and  $RMSEP = 0.25 \text{ m}^2/\text{m}^2$  corresponding to 8.4% of the GAI range).

**Fig. 11.** Relationships between NDVI and GF when considering all the pixels at the 8.8 cm resolution (a), and between NDVI and GAI when considering the 50% darkest green pixels at the 7 cm resolution (b). In both cases, VIs are computed by averaging pixel-level VI values. Prediction performances obtained using linear (in black) and best non-linear (in red, power function for GF and exponential function for GAI) regressions are shown. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

#### 4. Conclusions and perspectives

This study focuses on the estimation of leaf chlorophyll content from reflectance observations using an empirical approach applied to sugar beet crops. It is clearly demonstrated that computing the spectral indices over the well-illuminated green pixels of the image improves the sensitivity to chlorophyll content and decreases the possible impact of variations in canopy structure. Further, the  $mND_{blue}[728,850]$  index performs significantly better than every other index tested. This index has two interesting properties: (1) as a ratio index,  $mND_{blue}[728,850]$  is by construction independent to any factor that affects the radiance reflected by the canopy in a multiplicative way, including slope effects and variations in illumination conditions due to slight cloud coverage; (2) the particular selection of wavebands enhances the sensitivity of  $mND_{blue}[728,850]$  to leaf chlorophyll content while minimizing the impact of canopy structure. It is symptomatic to observe that the best-performing index for chlorophyll content estimation ( $mND_{blue}[728,850]$ ) is the poorest one for canopy structure retrieval. Reciprocally, the best index for canopy structure retrieval (NDVI) offers the poorest performances for chlorophyll content estimation. The main drawback of this type of spectral index based on a blue band is its sensitivity to variations in the spectral distribution of incident light: the latter may be indeed strongly influenced by changing illumination conditions that affect the scattering by aerosols, water droplets or crystals. Great attention should therefore be paid either to the stability of irradiance conditions (using potentially artificial light sources), or to the radiometric calibration that will require frequent measurements over reference panels or corrections from ancillary information. Alternatively, the use of a red reference located in the domain of maximum chlorophyll absorption (i.e., around 680 nm) may decrease the sensitivity to atmospheric conditions while providing interesting results if the spatial resolution and  $C_{ab}$  range are such that this band nearly saturates for every sample. Incidentally, another drawback of using a blue reference is that poor estimation performances may be expected for very low values of leaf chlorophyll content, as in this case, the blue waveband does not reach saturation and varies with chlorophyll content (Sims and Gamon, 2002).

Studying the impact of spatial resolution on  $C_{ab}$  estimation shows that  $mND_{blue}[728,850]$  may be quite sensitive to the soil influence. In the case of sugar beet crops, similar results are obtained for all the spatial resolutions finer than 4.4 cm, but these results deteriorate for coarser resolutions. In the context of UAV-based remote sensing, this means that a resolution of about 4 cm offers a good compromise between accuracy and efficiency, the latter improving as spatial resolution decreases and flight altitude increases. This compromise should, however, be

defined for each situation: for example, time constraints may be such that efficiency can be improved by reasonably decreasing spatial resolution and, therefore, accuracy (note that this decrease can somehow be compensated by choosing a shorter  $C_{ab}$ -sensitive waveband so as to mitigate the soil influence).

These results are derived from a comprehensive set of experiments including several locations, years, cultivars and levels of nitrogen fertilization. Good robustness properties are thus expected for sugar beet crops. However, these results need to be further evaluated for other species. In particular, the spatial resolution to be retained should be adapted to each crop to limit the fraction of mixed pixels in the computation of the spectral index. Also, the influence of the pixel subset used to compute the VIs should also be questioned for vegetation species exhibiting strong leaf surface effects, although this is already the case for the glossy sugar beet leaves. Ultimately, the proposed principles to derive optimal spectral indices could be extended to the estimation of other leaf biochemical constituents such as leaf water content: for example, the  $C_{ab}$ -sensitive waveband (728 nm) could be replaced by a water-sensitive one.

The rapid emergence of UAVs has opened a new era of Earth observation for vegetation monitoring (Houborg et al., 2015). Multi- and hyperspectral cameras are now becoming efficient and affordable sensors, and their combination with UAVs enables the acquisition of spectral data with the required high spatial resolution while providing a significant spatial coverage capacity in a reasonable time. This is particularly interesting for agricultural applications (Duan et al., 2014; Verger et al., 2014; Zarco-Tejada et al., 2013) that require a timely revisit capacity to sample the crop at the optimal development stage (Inoue et al., 2012). The VIs developed in this study take advantage of such high spatial resolution data to improve the estimation of leaf chlorophyll content in sugar beet canopies as compared to classical VIs of the literature. In particular, the use of  $mND_{blue}[728,850]$  based on UAV observations is promising to accurately estimate leaf chlorophyll content over larger areas.

#### Acknowledgments

This study was funded by the French Ministry of Agriculture, Agrifood, and Forestry (PHENOBET project, reference AAP RT 2014 no. 1415), and by the French National Research Agency, within the program “Investissements d’avenir” with the reference ANR-11-BTBR-0007 (AKER project). Thanks a lot to the three anonymous reviewers for their valuable comments and suggestions, as well as to Daniel Moura, David Bastidon and Jean-François Bonicel for their help in the experiments.
